The Research Institute of Applied Economics (IREA) in Barcelona was founded in 2005, as a research institute in applied economics. Three consolidated research groups make up the institute: AQR, RISK and GiM, and a large number of members are involved in the Institute. IREA focuses on four priority lines of investigation: (i) the quantitative study of regional and urban economic activity and analysis of regional and local economic policies, (ii) study of public economic activity in markets, particularly in the fields of empirical evaluation of privatization, the regulation and competition in the markets of public services using state of industrial economy, (iii) risk analysis in finance and insurance, and (iv) the development of micro and macro econometrics applied for the analysis of economic activity, particularly for quantitative evaluation of public policies.

IREA Working Papers often represent preliminary work and are circulated to encourage discussion. Citation of such a paper should account for its provisional character. For that reason, IREA Working Papers may not be reproduced or distributed without the written consent of the author. A revised version may be available directly from the author.

Any opinions expressed here are those of the author(s) and not those of IREA. Research published in this series may include views on policy, but the institute itself takes no institutional policy positions.

Given the structural differences in banking sector and financial regulation at country level in European Economic and Monetary Union (EMU), this paper tries to estimate the banking sector risk behavior at country level. Based on contingent claim literature, it computes "Distance-to-default (DtD)" at bank level and analyses the aggregate series at country level for a representative set of banks over the period 2004-Q4 to 2013-Q2. The indices provide an intuitive, forward-looking and timely risk measure having strong correlations with national/regional market sentiment indicators. An underlying trend exists but causality tests suggest no systemic component. Cross-sectional differences in DtD suggests fragility in EMU countries 12-18 months prior to the crisis and better predictive ability than the regulatory index based on large and complex banking institutions at European level. Furthermore, we explore the reasons for this divergence using VAR estimates.

*JEL classification:* G01, G13, G21, G28 *Keywords:* contingent claim analysis, Distance-to-default, banking risk

#### Acknowledgements

We are very grateful to Analistas Financieros Internacionales for kindly providing the credit rating dataset and Fernando Fernández-Rodríguez for his research assistance. We thank Scott R. Baker, Raquel Lopez, Eliseo Navarro, Vito Polito, Michael R. Wickens and the European Central Bank for allowing us access to their datasets. We also thank 6th International IFABS Conference participants and especially Stefan Eichler and Karol Sobanski for helpful comments. This paper is based upon work supported by the Government of Spain under grant numbers ECO2011-23189 and ECO2013-48326 and Fundación Banco Sabadell.

#### 1. Introduction

The 2007-08 financial crisis and the subsequent European sovereign debt crisis have exacerbated the need to understand and monitor the bank risk behavior. Renewed attention is being focused at the global scale to enhance and extend risk measurement methodologies. The eurozone is no exception and the twin objective of the European Central Bank (ECB) - price and financial system stability - places a strong emphasis on Systemically Important Financial Institutions (SIFI) but relies on individual countries' central banks to supervise smaller financial institutions.

This paper deviates from this current and in our view excessive focus and attention on detecting and monitoring risk at European banking level. We take a step backward and introduce a micro approach to document and monitor the buildup of banking sector risk at country level. Based on contingent claims literature, we calculate "Distance-to-default (DtD)" at bank level and analyze the aggregate series at country level for a representative set of banks over the period 2004-Q4 to 2013-Q2. Conceivably, if regulators pay greater attention to country-specific buildups of risk and their connectedness, they might take actions earlier to mitigate the extent and impact of future crisis.

There are many reasons for this choice. First, the structure of the banking sector within EMU countries varies considerably. In the case of Germany, Finland and the Netherlands, total banking sector assets are relatively concentrated, while in Italy, Greece, France and Austria, they are distributed quite equitably. Figure 1 summarizes this information by plotting the relative size of banking firms (by total assets in 2010) in individual EMU countries, where the total asset of the biggest bank in a particular country is normalized to one. Excessive asset concentration lowers regulatory cost but makes countries vulnerable to the actions of individual institutions.

## [Figure 1 about here.]

Second, countries economic dependence on the banking sector varies drastically. Consider the case of Luxembourg, where the total financial assets under management is roughly 25 times the Gross Domestic Product (GDP) at current prices while, in Greece, Italy and Finland, this multiple is less

 $<sup>^{1}\</sup>mathrm{We}$  consider total asset managed by banking firms as a proxy for relative economic dependence.

than three (Figure 2a). In some countries, all financial services are provided by banks, while in others there are specialized mortgage, pension and insurance companies. Given the existence of deposit insurance at the national level, governments implicitly or explicitly guarantee bank deposits; which in times of stress, can transfer huge contingent liabilities onto sovereign's balance sheets and bailing out may lead to the weakening of government's own position.

### [Figure 2 about here.]

Third, the excessive home bias in European banks' asset portfolios (Figure 2b) creates a vicious circle for risk transfer between banks and sovereigns, which creates perverse economic and political incentives for government to save domestic banks. The existence of financial regulation at national level provides governments with the means to pursue their own national interests. Also noteworthy is the home bias in the private investors portfolio (Belke and Schneider (2013)) which aggravates this problem further. Neighborhood effects, close connectedness with certain countries and cross country differences in bailout strategy also motivate the monitoring of bank risk at country level.

Given this background, the main objective of the paper is to document the evolution of country level banking risk indices. The central questions addressed here are: (1) Does this risk measure provide useful information on the buildup of risk?; (2) Does it render utile insights into market sentiments?;

- (3) Can it perform better than regulatory measure of prudential risk?; and
- (4) Is there strong dependence among countries banking sector?

As it turns out, country level DtDs are simple, convenient and intuitive forward looking risk measures. The level of DtD differentiates countries based on the structural differences in their financial sectors and shows strong correlations with national and regional market sentiments. The improved informational content helps it outperform the regulatory risk measures based at European level and the causal linkages run from aggregate country level DtDs to Euro wide regulatory indicators. The country level DtDs do show very high correlations but causality and connectedness tests reveal no systemic component. This supports our argument of the need to measure risk indices at country level.

This paper contributes to the literature in several ways: (1) we use a novel bottom-up approach to understanding systemic risk buildup in the

banking sector and risk-shifting behavior in EMU countries; (2) we use one of the most comprehensive representative databases for the EMU financial sector; (3) we do not neglect the banking sector of smaller countries, which may not be relevant at EMU level but will be relevant at country level; and (4) to our knowledge, this is the first paper which tries to establish a link between country-specific buildup of financial risk with euro-wide aggregate risk indicators and national and regional market sentiments.

The rest of the paper is organized as follows. Section 2 reviews the prior literature that used different frameworks to understand bank fragility and justifies our selection of DtD as banking risk indicator. Section 3 describes the sample data used to construct, analyze and calibrate the individual and aggregate DtD series. Section 4 first documents the behavior of returns, volatility and DtD for each EMU country; it then analyses these behaviors jointly and presents some cross-sectional econometric analysis to gauge the predictive ability and market association of the country-specific DtD indicators. Section 5 documents the connectedness among country level banking risk. Section 6 draws conclusions.

#### 2. Choice of risk indicator

Based on the survey of the existing risk measure techniques, we employed three basic criteria for indicator selection. It should: (1) identify the existing balance sheet fragility; (2) incorporate uncertainty using forward looking market measure; and (3) provide quantifiable risk indicators to assess relative creditworthiness (Gapen et al. (2005)). A comprehensive literature survey suggest that most of bank risk indicators can be classified into two broad categories.

The first or the traditional approach to assess the risk of a firm are based on the pure balance sheet data (see Altman (1968), Altman and Katz (1976), Kaplan and Urwitz (1979), Ohlson (1980), Zmijewski (1984), Blume et al. (1998) among others). Key accounting ratios are identified and using multivariate discriminant or multinomial choice models, firm's default probability is estimated. However the consensus on the accuracy and stress prediction ability of these indicators are relatively low.

These models have generally been criticized on three grounds: (1) the absence of a underlying theoretical model; (2) the timeliness of the infor-

mation;<sup>2</sup> and (3) the lack of uncertainty and forward-looking component. The selected methodologies also introduce sample selection bias, generating inconsistent coefficient estimates (e.g., Shumway (2001), Chava and Jarrow (2004), Thomas et al. (2012)).

The second approach is pure market based. These are indices determined directly in the market place (e.g. stock prices, aggregate realized volatility, aggregate market leverage, turbulence (a measure of excess volatility relative to market), liquidity ratios and credit condition (e.g., credit default swaps)). Most of these measures lack an underlying theoretical framework but the timely availability and continuous incorporation of information helps improve the relative performance and predictive ability in some cases (see Agarwal and Taffler (2008), Campbell et al. (2011), Gropp et al. (2006), Jorion (2006), Vassalou and Yuhang (2004)).

In between these measures lies the contingent claims based model (CCA) of Merton (1974) which provides a theoretical underpinning and answers some of these criticisms. The basic model is based on the priority structure of balance sheet liabilities and uses the standard Black-Scholes option pricing formula to value the junior claims as call option on firms' value with the value of senior claims as default barrier. The structural underpinning and the combination of market-based and accounting information helps obtain a comprehensive set of financial risk indicators, e.g. DtD, probabilities of default, credit spreads, etc.

Additionally, this measure captures the current period instability (using volatility), a forward-looking component (using stock prices) and balance sheet mismatch (using capital structure), in accordance with our requirements. It has been widely applied to assess the ability of corporates, banks and sovereigns to service their debt. Banking applications follow CCA by interpreting a bank's equity as a call option on its value given the limited liability of shareholders. This approach was further refined by Vasicek (1984) and Crosbie and Bohn (2003) and is applied professionally in Moody's KMV to predict default.

The DtD approach has been widely cited and reviewed by the International Monetary Fund (IMF), European Central Bank (ECB) and Office

<sup>&</sup>lt;sup>2</sup>These models use information from financial statements which are based on past performance and are available only at a quarterly or an annual frequency; thus, they fail to capture changes in the financial conditions of the borrowing firm.

of Federal Research (OFR) as a tool for enhancing bank risk analysis. A number of applications of this approach have been studied to analyze different dimensions of risk. Several papers have examined the usefulness of DtD as a tool for predicting corporate and bank failure (Jessen and Lando (2015), Koutsomanoli-Filippakia and Mamatzakis (2009), Qia et al. (2014), Kealhofer (2003), Oderda et al. (2003), Vassalou and Yuhang (2004), Gropp et al. (2006), Harada et al. (2010), Thomas et al. (2012)). They have found DtD to be a powerful measure to predict bankruptcy and rating downgrades. Comparative analysis of DtD (Hillegeist et al. (2004), Campbell et al. (2008), Bharath and Shumway (2008), Vassalou and Yuhang (2004), Jessen and Lando (2015) and Agarwal and Taffler (2008)) also suggests that DtD can be a powerful proxy to determine default.

#### 2.1. Calculation methodology

The foundation for this model lies with the structural model of default developed by Black and Scholes (1973) and Merton (1974). Since equity is a junior claim to debt, it can be modeled and calculated as a standard call option on the assets with exercise price equal to the value of risky debt (also known in the literature as distress barrier or default barrier).

The model uses no arbitrage conditions and assumes a frictionless market. The stochastic process generating the firm's assets return are described by the diffusion process with a constant variance per unit time  $(\sigma_A)$ . Following standard literature, we assume that financial distress and bankruptcy are costless.<sup>3</sup> A firm has a simple capital structure with N shares of common stock with market capital E and zero coupon bonds with a face value of D with time to maturity T. The estimation methodology is as follows.

We use the value conservation equation:

$$A = E + De^{-rT} \tag{1}$$

Given the assumption of assets distributed as a Generalized Brownian Motion, the application of the standard Black-Scholes option pricing formula (Black and Scholes (1973)) yields the closed-form expression:

$$E = AN(d_1) - e^{-rT}DN(d_2)$$
(2)

<sup>&</sup>lt;sup>3</sup>Here we assume that equity market price will reflect the cost of bankruptcy.

where r is the risk-free rate under risk-neutrality, and N(\*) is the cumulative normal distribution. The values of  $d_1$  and  $d_2$  are expressed as:

$$d_1 = \frac{\ln(\frac{A}{D}) + (r + 0.5\sigma_A^2)T}{\sigma_A \sqrt{T}}$$
(3)

$$d_2 = d_1 - \sigma_A \sqrt{T} \tag{4}$$

The Merton model uses an additional equation that links the asset volatility  $\sigma_A$  to the volatility of the bank's equity  $\sigma_E$  by applying Ito's Lemma:

$$\sigma_E = N(d_1) \frac{A}{E} \sigma_A \tag{5}$$

Using Eqs. 2 and 5, we obtain the implied asset value A and volatility  $\sigma_A$ , by inverting the two relationships. Once numerical solutions for A and  $\sigma_A$  are found, the T periods ahead DtD is calculated as:

$$DtD = \frac{A - D}{\sigma_A A} \tag{6}$$

DtD can be interpreted as the number of standard deviations the value of a firm's asset is away from its default barrier. This standardization across firm size and volatility can be used to rank firms in terms of their relative credit worthiness. The three key inputs in calculating the DtD (market capitalization, debt, and the volatility of equity) implies that it can be influenced by the leverage ratio (debt/(equity + debt)) and volatility of the firm. A higher value of DtD can be obtained either because the leverage of the firm is low or because the volatility is low or both (Figure 3).

## [Figure 3 about here.]

As can be noted, at a fixed level of volatility and low levels of leverage, DtD changes are small and insignificant for changes in leverage; while for a constant level of leverage, DtD shows much sharper drops for changes in equity volatility. This implies that more than leverage, it is equity volatility that has a greater influence in driving large changes in DtD (Thomas et al. (2012)). Note that here we don't intend to improve the performance of this risk measure technique but aim to use it more effectively in order to capture the banking sector fragility. This approach will help supplement the existing methodologies that failed to capture vulnerabilities prior to this crisis.

#### 3. Data

The sample selection methodology is as follows: First, an exhaustive list of all listed and delisted monetary financial institutions is selected from Bankscope<sup>4</sup> database (as on 10<sup>th</sup> February 2014). We obtain a total of 199 firms in western Europe. Secondly, only firms whose shares were publicly listed and traded between the last quarter of 2004 till the second quarter of 2013 and are headquartered in EMU countries are selected. Finally, credit institutions which are pure-play insurance, pension or mortgage banks are removed. To formalize this decision, we use Datastream as an additional source of information. The major reason for this exclusion is the difference in liability structure and business model compared to banks. However it doesn't mean that they are less risky to the financial system.

This choice also ensures that the selected banks share the same accounting currency. However, it does not mean that they have a similar exchange rate risk profile, since the level of foreign currency exposure will depend on their respective asset profiles. The market-based data include daily observations of risk-free interest rates, daily stock price and total outstanding share in public. The list of variables and data sources are summarized in Table 1.

## [Table 1 about here.]

Firms which were listed, delisted, nationalized or suffered any other relevant corporate actions are considered in the data set until they stopped trading on public exchanges. Due to the varying number of corporate actions every quarter, the number of firms in the sample changes over time, both for the full sample and for individual countries (Figure 4) though the core banks remains the same over time. They have an aggregate weight of 78% at the beginning of 2006 and of 86% at the end of it 2013-Q2. Therefore, we honestly do not think that changes in the bank sample composition over time may have a relevant impact on the forecasting properties of the dataset. The comprehensive list of firms used in this analysis is summarized in Table 2.5 This detailed list of firms represents one of the best references for the EMU banking sector.

<sup>&</sup>lt;sup>4</sup>It provides a comprehensive balance sheet data for financial companies.

<sup>&</sup>lt;sup>5</sup>The period for which each firm was traded is also available but is not presented here in order to save space. This information is available from the authors upon request.

#### [Table 2 about here.]

## [Figure 4 about here.]

Computation of individual DtD: DtD is not measured directly; it is recovered implicitly from the balance sheet and market price of firm's liabilities. For our analysis we compute DtD at quarterly frequency. In practical terms, this means that the balance sheet information has to be modified from its original quarterly, half-yearly, or in few cases, yearly frequencies using cubic spline interpolation. Also the real debt contracts are not all written with a single terminal date. To overcome this problem, a common procedure used by Moody's KMV (Vasicek (1984)) and also employed here, is to adopt a one year horizon (T=1), but to weight longer term debt (maturity > 1) year) at only 50% of face value. The debt barrier (D) will then be equal to the face value of short-term liabilities plus half of the long-term liabilities. Equity value of the firm (E) is computed as the quarterly average of daily market capitalization (number of common shares x share prices) while quarterly historical volatility based on daily log-returns is taken as equity volatility  $(\sigma_E)$ . The individual DtD is then calibrated using the procedure outlined in Section 2.

Aggregating DtD series: In practice, the extension of DtD series as a system wide indicator has two major difficulties: (1) At what level should they be aggregated? Since we aim to focus on country level risk measurement in EMU, we would aggregate the DtD at country level; and (2) How can individual banks' data be aggregated as a system-wide representation? Here we follow Saldias (2013), Harada and Ito (2008) and Harada et al. (2010), and take the simple cross-sectional equal-weighted average at each point in time for all banks headquartered in a particular country as the aggregated risk measure. The simple average DtD for country i at time t is represented by  $aDtD_{i,t}$ :

$$aDtD_{i,t} = (1/N) \sum_{j=1}^{N} DtD_{j,t}$$
 (7)

where  $DtD_{j,t}$  is the individual DtD for firm j at time t having headquarter in country i.

This aggregation approach offers relative risk measures and is very attractive in terms of policy advice. However, this methodology has two major drawbacks. First, it ignores the latest modifications in DtD measurements

to improve its relative performance (see Jessen and Lando (2015), Gray and Malone (2008) and Saldias (2013)). Since our focus is not on performance improvement of DtD, we took the most basic and intuitive measure to understand bank risk. Secondly, it doesn't incorporate the joint distribution properties (see Gray et al. (2007), Gray and Jobst (2010), Duggar and Mitra (2007), Gray et al. (2010) and Jobst and Gray (2013)). Since our aim here is to evaluate the underlying linkages among country level risk, we don't incorporate a priori dependence structure among banking institutions in our aggregation technique.

Country-level aDtD: To visualize the country-wise banking risk behavior, we plot the aDtD for individual EMU countries (Figure 5). As can be seen, the level of aDtD differs considerably across countries. The series together show a trend and the variability across time is high. The pre-crisis level of aDtD is high (above 4) for almost all countries with Greece, Austria and Ireland at the lower end. During the crisis period, all countries saw corrections in aDtD with Ireland, the Netherlands, Austria and Greece showing huge drops in aDtD level. Post 2007-08, the graph also suggest that the level of aDtD remain low for most of the countries suggesting that it is able to catch the trend and fluctuations during the current crisis.

[Figure 5 about here.]

#### 4. Analysis

#### 4.1. Does aDtD provide information regarding risk buildup?

As banking stress indicators, we compare the evolution of aDtD with banking sector equity and volatility indices.<sup>6</sup> Figure 6 plots aDtD, bank equity index and volatility for each EMU country separately. The left axis represents the equity index level while the right axis represents the annualized volatility in percentage. The level of aDtD is scaled to show the general trend

<sup>&</sup>lt;sup>6</sup>The country wise bank equity index is based on average logarithmic returns of all publicly traded banking firms headquartered in a particular country and are normalized to 100 for all countries at the beginning of the last quarter in 2004. The volatility is equal weighted annualized equity price volatility based on the standard deviation of daily logarithmic returns of the previous quarter. This methodology creates an upward (downward) bias in the returns (volatility) indices due to bank failures and should be interpreted carefully.

and variation with time. The graphs suggest that aDtD started deteriorating for most countries between 2006-07, except for France and the Netherlands. Notably, it started declining when bank index level showed an upward trend while volatility was quite stable.<sup>7</sup>

## [Figure 6 about here.]

The returns level suggests that the bank equity prices have fallen substantially for all countries. The first period of rapid decline started around mid 2007, though some recovery was seen in 2009. The second period of decline started during the sovereign debt crisis at the end of 2009, and still continues for some countries. For almost half of the sample, the index level at the end of 2012 is below the index value at the end of 2004. Greece, Belgium, Ireland, Portugal and Italy witnessed the highest drop while Finland and Austria were largely unaffected. In some countries (like Portugal and Ireland) the index level shows a dramatic recovery post crisis. These spikes are due to the sudden drop in sample size due to bank failures and are therefore more notable for small countries having fewer banks.

The volatility of small countries (Greece, Portugal, Ireland, the Netherlands and Austria) is relatively high. Post 2009, the volatility dropped for most EMU countries but has not yet returned to its pre-crisis level. European sovereign debt crisis, loss of market confidence and the need for continuous monetary support to banking sector may be explanations for the relatively high average volatility in peripheral countries. Given the changes in the sample size in a few peripheral countries, the shift in the mean volatility level needs to be interpreted with caution.

Equity indices and aDtD during the crisis: To compare the performance of equity indices with aDtD during the crisis, we analyze the country-wise behavior of market returns with aDtD during the financial crisis. As a predictive indicator of future health, we examine the possibility by comparing the cumulative returns from 2007-Q2 and 2008-Q2 to 2009Q1 with the fall in level of aDtD indicator in each country. Figure 7a summarizes this information aptly. As can be seen, most of the fall in aDtD occurred between 2007-Q2 and 2008-Q2, indicating a direct obvious prediction of vulnerability

 $<sup>^{7}</sup>$ It also indicates strong correlations with the average volatility, which undermines its effectiveness.

prior to the crisis. However, the total drop in returns shows no correlation with the drop in aDtD.

Do initial level of aDtD matters?: Whether or not the initial level of aDtD matters, we plot the initial level of aDtD with the drop in aDtD during the crisis (Figure 7b) and find a positive relationship. This suggests that higher initial levels of aDtD experienced higher corrections during this period. The aDtD for most EMU countries averaged between 4 to 5 prior to the crisis. During the crisis (between 2007-Q2 and 2009-Q1), it fell sharply for Austria, France and Italy while for Portugal, Spain and Greece, the corrections were lower than expected.

## [Figure 7 about here.]

#### 4.2. Does aDtD render utile insights into market sentiments?

Here we explore the association of aDtD with a selection of indicators covering broad market sentiments and sectoral bank indices collected from independent agencies, professional market data providers and other academic authors.

At country level: We consider six variables as proxy for market sentiment: a consumer confidence indicator (CCI), stock returns (RET), the credit rating (RAT), a fiscal stance indicator (FSI), stock volatility (VOL), rating (RAT) and an index of economic policy uncertainty (EPU). As for the national bank indices, we examine two sectoral equities indices covering banks and financial services (Table 3).

Table 4 shows that for the individual countries we find a positive association between aDtD, CCI and RET. In 7 out of 11 cases we detect a strong connection between our indicator and CCI, while for the RET we obtain a moderate or strong relationship in 6 out of 11. We also find a relatively moderate negative association with RAT and EPU and a strong negative correlation with VOL. For FSI we obtain mixed results. For the sectoral bank indices, regardless of the DtD indicator, our results suggest a moderate positive association with both DSBANKS and DSFIN. The findings suggest that aDtDs are capturing the underlying trends that generate differences in risk perceptions of national banking system.

[Table 3 about here.]

[Table 4 about here.]

At regional (Eurozone) level: We did a similar exercise to understand the association between regional market sentiments and financial indicators with aDtD. We find a strong positive association between aDtDs and the regional consumer confidence indicator and a strong negative relationship with regional economic policy uncertainty and regional financial market volatility. The associations with the indicator of credit quality in the EMU corporate market and regional fiscal stance are moderate and positive while their connection with regional interest rate volatility (1-year forward) is mixed. Regarding the regional sectoral bank indices, there is evidence of a strong association with aDtDs in most cases. Interestingly, the aDtDs in the peripheral countries strongly influence all EMU bank indices (both GIIPS<sup>8</sup> and non-GIIPS), suggesting a strong co-movement tendencies among banking indices.

## 4.3. Can aDtD perform better than regulatory measure of prudential risk?

We examine how country-wise aDtD perform with respect to the European SIFI based aggregate banking risk indicator (ECB DtD) used by the European Central Bank. To check the better predictive ability of aDtD, we plot the ECBDtD together with aDtD in Figure 5. The graphical evidence suggests that aDtDs do suggest the deteriorating market conditions in most peripheral EMU countries (Spain, Ireland, Greece and Italy) and some central countries (Germany, Belgium and Finland) prior to the ECBDtD.

An additional dimension of considering comprehensive list of banks for each country is the increased informational content. To test whether this has a significant effect, we create a time-series of average DtD of all EMU banks in our sample (EMU-aDtD) and explore its relationship with the EMU macroeconomic uncertainty indicators compiled by the European Central Bank (2013) from a set of diverse sources: (1) measures of uncertainty perceived by economic agents about the future economic situation based on surveys; (2) measures of uncertainty or of risk aversion based on financial market indicators; and (3) measures of economic policy uncertainty. As far as the EMU banking risk measure is concerned, we use the ECBDtD.

Regarding the measures of uncertainty related to future economic outcomes, we use the degree of disagreement about the projections for activity

<sup>&</sup>lt;sup>8</sup>Greece, Ireland, Italy, Portugal and Spain.

<sup>&</sup>lt;sup>9</sup>Complete detail of regional indices and correlations are not attached to save space but are available upon request.

between professional forecasters measured as the standard deviation of the projections from Consensus Economics for annual real GDP growth in the following calendar year (ECBANY), the average "aggregate uncertainty" from the ECB's Survey of Professional Forecasters (ECBBAVE), combining both disagreement between forecasters and individual uncertainty, and an indicator capturing the uncertainty of private households (ECBCHOU) and enterprises (ECBCBUS) based on the European Commission's Business and Consumer Surveys. Additionally, to account for the concerns for the stability of the euro we have used the indicator built up by Klose and Weigert (2012) which reflects the market expectation of the probability that at least one euro area country will have left the currency union by the end of 2013 (EUROINST).

To assess financial market uncertainty or risk aversion measures, we use an average of a set of financial market indicators (implied bond and stock market volatility, implied EUR/US dollar volatility and CDS spreads over government bond yields) and a number of systemic stress indicators (exchange rate volatility, equity market volatility, bond market volatility, money market volatility, financial intermediation and a composite systemic stress indicator) (ECBDAVE).

With respect to economic policy uncertainty, we use an index based on the newspaper coverage of policy-related economic uncertainty and the disagreement between forecasters with regard to the outlook for inflation and budget balances: These components are aggregated using weights of 50% for the former and 25% for each of the dispersion measures (ECBEAVE). Additionally, we make use of an indicator that combines all the individual sets of series by principal component analysis (ECBFPC). We select these measures of uncertainty because they show a significant negative correlation with key macroeconomic variables, such as quarterly growth rates of real GDP, total investment, private consumption and, in particular, total employment.

Table 5 summarizes the correlations of these ECB regulatory indicators with EMU-aDtD. As can be seen, we find a significant and negative association between our indicators of EMU banking risk based on DtD and the various measures of macroeconomic uncertainty, suggesting that higher banking risk (signaled by a reduction in DtD) will increase macroeconomic uncertainty and, as a consequence, adversely affect macroeconomic events.

To test the predictive ability of this indicator with respect to the regulatory indicators, we assessed the possible existence of Granger-causality. As can be seen in Table 6, with the sole exception of ECBCHOU, we find a significant unidirectional Granger-causality relationship running from our indicators of EMU banking risk to both the various measures of macroeconomic uncertainty and the banking risk indicator used by the ECB. This result gives further support to the hypothesized interconnection between DtDs and macroeconomic uncertainty and banking risk.

[Table 5 about here.]

[Table 6 about here.]

Summary: Our empirical estimates using country level indices suggest that the country-wise aDtD has better predictive ability than the market based measures (returns and volatility) and is strongly connected with market sentiments at national and regional level. The initial level of aDtD matters and the drop is more significant for countries having higher aDtD. aDtD also have strong correlations with regulatory measures of risk and has higher information content. The direction of causality runs from aDtD to regulatory measures.

## 5. Connectedness among countries banking risk

In this section, we explore the linkages between aDtD using a cross country connectedness measures. We use three ways to measure the connectedness: (1) Correlations; (2) Granger causality; and (3) Diebold-Yilmaz connectedness index (DYCI) based on the variance decomposition of forecast errors.

#### 5.1. Correlation measures

To understand the co-movement properties, we use three correlation measures (parametric: Pearson, and non-parametric: Spearman and Kendell) in our analysis.<sup>10</sup> Since the Pearson measure is the most commonly used, we report our findings based on Pearson correlations only, but they are also robust based on other measures.

[Table 7 about here.]

<sup>&</sup>lt;sup>10</sup>This avoids any bias arising from potential non-linear dependencies and confirms the robustness of our findings.

For each measure of correlations, we first estimate the pair-wise correlations between the aDtD (Table 7). As can be seen, we find a strong correlation<sup>11</sup> between indices, which suggests a common risk factor. This may also be due to the small sample, which contains two crisis episodes. To understand the time varying correlation dynamics, we tested for correlations using pre-/post crisis windows and apply a signed rank test to evaluate the null hypothesis that the mean and median correlations are equal if we divide the time period in two half (pre and post 2009-Q4).

The results suggest that except Germany and Finland, all other countries shows very strong correlations with EMU average. This also suggest a common risk factor which we test in the next section. Belgium, Greece, Italy and Portugal have strong inter-linkages and connections across the board. Belgian banking sector shows strong connections with all EMU countries except Germany and the Netherlands. Germany is strongly connected with only Italy and moderately to France, Austria and Finland. For other peripheral countries, Germany has weak correlations.

#### 5.2. Granger causality

The graphic behavior of the countries' aDtD series and correlation estimates suggests an underlying trend. It may be due to an increase in the systemic risk of global financial industry due to cross linkages, increased volatility or investment in correlated assets. To understand this spillover within the EMU banking sector, we run Granger causality tests for each pair-wise country aDtDs. We find very weak evidence of causality running from a particular country towards the rest of the countries (Figure 8), which suggests that the banking risk captured by countries' aDtDs remains idiosyncratic (suggestive evidence of no systemic component). To test the robustness of our results, we also did the analysis based on banks' market capital and asset based weighted average DtD. The results (not shown here to save space, but they are available from the authors upon request) render the same qualitative conclusions than in the case of using aDtDs.

[Figure 8 about here.]

 $<sup>^{11}</sup>$ We use the adjective "strong" when the absolute value of the correlation is above 0.8, "moderate" when it is between 0.7-0.8, and "weak" when it is between 0.6-0.7.

#### 5.3. Diebold-Yilmaz connectedness measure

To explore further the systemic underlying component among aDtD indices, we use VAR (vector auto regression) methodologies based measure of connectedness. The connectedness is based on the decomposition of the forecast error variance, which is briefly described here. For a multivariate time series, the forecast error variance decomposition works as follows: First, we fit a standard vector autoregressive (VAR) model to the series; secondly, using series data up to, and including, time t, establish an H period ahead forecast (up to time t + H); and finally, decompose the forecast error variance for each component with respect to shocks from the same or other components at time t.

Consider an N-dimensional covariance-stationary data-generating process (DGP) with orthogonal shocks:

$$x_{t} = \Theta(L)u_{t}, \Theta(L) = \Theta_{0} + \Theta_{1}L + \Theta_{2}L^{2} + ..., E(u_{t}, u'_{t}) = I$$

Note that  $\Theta_0$  need not be diagonal. All aspects of connectedness are contained in this very general representation. Contemporaneous aspects of connectedness are summarized in  $\Theta_0$  and dynamic aspects in  $\Theta_1, \Theta_2, ...$  Transformation of  $\Theta_1, \Theta_2, ...$  via variance decompositions in needed to reveal and compactly summarize connectedness. Let us denote by  $d_{ij}^H$  the ij-th H-step variance decomposition component (i.e., the fraction of variable i's H-step forecast error variance due to shocks in variable j). The connectedness measures are based on the "non-own" or "cross" variance decompositions,  $d_{ij}^H, i, j = 1, ..., N, i \neq j$ .

Diebold and Yilmaz (2014) propose several connectedness measures built from pieces of variance decompositions in which the forecast error variance of variable i is decomposed into parts attributed to the various variables in the system. Here we provide a snapshot of their connectedness index. They proposed a connectedness table such as Table 8 to understand the various connectedness measures and their relationships. Its main upper-left NxN block, that contains the variance decompositions, is called the "variance decomposition matrix," and is denoted it by  $D^H = [d_{ij}]$  The connectedness table augments  $D^H$  with a rightmost column containing row sums, a bottom row containing column sums, and a bottom-right element containing the grand average, in all cases for  $i \neq j$ .

[Table 8 about here.]

The off-diagonal entries of  $D^H$  are the parts of the N forecast-error variance decompositions of relevance from a connectedness perspective. In particular, the gross pairwise directional connectedness from j to i is defined as follows:

$$C_{i \leftarrow j}^H = d_{ij}^H$$

Since in general  $C_{i \leftarrow j}^H \neq C_{j \leftarrow i}^H$  the net pairwise directional connectedness from j to i, can be defined as:

$$C_{ij}^H = C_{i \leftarrow i}^H - C_{i \leftarrow j}^H$$

Regarding the off-diagonal row sums in Table 8, they give the share of the H-step forecast-error variance of variable  $x_i$  coming from shocks arising in other variables (all other, as opposed to a single other), while the off-diagonal column sums provide the share of the H-step forecast-error variance of variable  $x_i$  going to shocks arising in other variables. Hence, the off-diagonal row and column sums, labeled "from" and "to" in the connectedness table, offer the total directional connectedness measures. In particular, total directional connectedness from others to i is defined as

$$C_{i \leftarrow \bullet}^H = \sum_{j=1, j \neq i}^N d_{ij}^H$$

The total directional connectedness to others from i is defined as

$$C_{\bullet \leftarrow i}^H = \sum_{j=1, j \neq i}^N d_{ji}^H$$

We can also define net total directional connectedness as

$$C_i^H = C_{\bullet \leftarrow i}^H - C_{i \leftarrow \bullet}^H$$

Finally, the grand total of the off-diagonal entries in  $D^H$  (equivalently, the sum of the "from" column or "to" row) measures total connectedness:

$$C^{H} = \frac{1}{N} \sum_{i,j=1, j \neq i}^{N} d_{ij}^{H}$$

For the case of non-orthogonal shocks the variance decompositions are not easily calculated as before because the variance of a weighted sum is not an appropriate sum of variances; in this case methodologies for providing orthogonal innovations like traditional Cholesky-factor identification may be sensitive to ordering. So, following Diebold and Yilmaz (2014), a generalized VAR decomposition (GVD), invariant to ordering, proposed by Koop et al. (1996) and Pesaran and Shin (1998) will be employed. The H-step generalized variance decomposition matrix is defined as  $D^{gH} = [d_{ij}^{gH}]$ , where

$$d_{ij}^{gH} = \frac{\sigma_{ij}^{-1} \sum_{h=0}^{H-1} (e_i^{'} \Theta_h \sum e_j)}{\sum_{h=0}^{H-1} (e_i^{'} \Theta_h \sum \Theta_h^{'} e_j)}$$

In this case,  $e_j$  is a vector with  $j^{th}$  element unity and zeros elsewhere,  $\Theta_h$  is the coefficient matrix in the infinite moving-average representation from VAR,  $\Sigma$  is the covariance matrix of the shock vector in the non-orthogonalized-VAR,  $\sigma_{ij}$  being its  $j^{th}$  diagonal element. In this GVD framework, the lack of orthogonality makes it so that the rows of do not have sum unity and, in order to get a generalized connectedness index  $\tilde{D}^g = [\tilde{d}^g_{ij}]$ , the following normalization is necessary:  $\tilde{d}^g_{ij} = d^g_{ij}/\sum_{j=1}^N d^g_{ij}$ , where by construction  $\sum_{j=1}^N \tilde{d}^g_{ij} = 1$  and  $\sum_{i,j=1}^N \tilde{d}^g_{ij} = N$ . The matrix  $\tilde{D}^g = [\tilde{d}^g_{ij}]$  permits us to define similar concepts as defined before for the orthogonal case, that is, total directional connectedness, net total directional connectedness and total connectedness.

Tables 9 and 10 present the connectedness tables for aDtD based on six months and one year horizon, along with the nonparametrically bootstrapped standard errors, while Figure 9 shows the most important directional connections among the pairs of  $12 \ aDtD$ s based on the top three deciles. As can be seen, all the connectedness measures are statistically different from zero at least at the 5% level. To test the robustness of our results, we also did the analysis based on banks' market capital and asset based weighted average DtD. The results (not shown here to save space, but they are available from the authors upon request) render the same qualitative conclusions than in the case of using aDtDs.

The Netherlands show very weak connectedness while Germany and Italy shows linkages only with Finland and Portugal respectively. Spain, Belgium, Portugal and Austria have high connectedness with most EMU countries except for the Netherlands, Italy and Germany. Even for changing horizon, the results remain quite consistent. In most cases, the effects seem to dry out but the connectedness pair remain the same. Finally, we observe a value of 73.67% for the total connectedness between aDtD in a horizon of 6 months

and value 76.72% for a year, in line with the values of 78.3% obtained by Diebold and Yilmaz (2014) for US financial institutions.

[Table 9 about here.]
[Table 10 about here.]
[Figure 9 about here.]

#### 6. Conclusion

By analyzing the behavior and fluctuations of a market based banking risk indicator for individual EMU countries, we find that aDtD is an intuitive, simple and convenient forward looking risk measure. The level of aDtD varies with country suggesting cross-sectional structural differences across the banking sector and captures trends as well as fluctuations in the financial markets. Analysis during the crisis period suggests better predictive ability (12-18 months prior to the crisis) for most of the EMU countries. The initial level of aDtD matters but the change in aDtD is more pronounced for countries with a higher initial level.

When compared with other regulatory risk and market sentiment measures, aDtDs shows better predictive ability and very high correlations. The strong association between aDtDs and regional (Eurozone) market sentiment (uncertainty)/sectoral banking indices also improves the explanatory power. The Granger causality test reveals the direction of causality running from aDtDs to Eurozone risk indicators (and not the other way round) suggesting better information content.

The correlations analysis suggests strong inter-linkages across country level banking stress but low inter-linkage between core and peripheral EMU countries. Taking s step further, we tested for a systemic component using Granger causality tests and found negative results. To better understand the dependence structure, we explored further by analyzing the connectedness using Diebold-Yilmaz Connectedness Index and found low connectedness among country level banking risk indices.

As the recent literature has highlighted huge connectedness among Systemically Important Financial Institutions (SIFI) and high degree of joint risk of default, our empirical estimates which uses country level indices suggest otherwise. The country-wise aDtD has higher predictive ability and

is strongly connected with market sentiments but the connectedness among the country-wise aDtD is low. Suggesting that the inter-linkages may be higher for SIFI but for the country level banking sector, the connectedness is low. This result will be beneficial for understanding and augmenting a priori dependence structure in the computation of systemic risk.

So, there are various reasons for considering country-wise risk indicators alongside regional market and other risk measures. As the statistical theory suggests, when faced with two estimators for the same underlying variable, it is optimal to combine the two. Tracking country specific indices provide additional information related to the average risk level and their ability to forecast the risk buildup cannot be ignored. Following the systemic risk indicators based on large, complex EU-wide financial institution may delay the prediction of risk buildup.

DtD measures can also be extended beyond the banking context. The theoretical argument being a kind of option value of waiting under uncertainty can be extended to international trade literature to help understand the impact of uncertainty on investment, export, import and employment (Belke and Gros (2001)) in EMU. Further extension can also help examine the interconnection between banking and sovereign risk in the euro area (Gómez-Puig et al. (2015)).

#### Acknowledgments

We are very grateful to Analistas Financieros Internacionales for kindly providing the credit rating dataset and Fernando Fernández-Rodríguez for his research assistance. We thank Scott R. Baker, Raquel Lopez, Eliseo Navarro, Vito Polito, Michael R. Wickens and the European Cenral Bank for allowing us access to their datasets. We also thank 6<sup>th</sup> International IFABS Conference participants and especially Stefan Eichler and Karol Sobański for helpful comments. This paper is based upon work supported by the Government of Spain under grant numbers ECO2011-23189 and ECO2013-48326 and Fundación Banco Sabadell.

Table 3: National financial indicators

Market sentiment indicators

Description

Variable

Stock Volatility (VOL)

Index of Economic Policy

Uncertainty (EPU)

This index is built up by the European Com-Consumer Confidence In-European dicator (CCI) mission which conducts regular harmonized Commission (DG ECFIN) surveys of consumers in each country. Stock Returns (RET) Differences between logged stock indices prices Datastream of the last and the first day of the quarter for each country. Rating (RAT) Credit rating scale built up from Fitch, Bloomberg Moodys, S&P ratings for each country. Following Blanco (2001), we built up a quarterly scale to estimate the effect of investor sentiment based on the rating offered by these three rating agencies. Index of Fiscal Stance This indicator compares a target level of the Provided by (FSI) debt-GDP ratio at a given point in the futhe authors ture with a forecast based on the government budget constraint. It was built by Polito and Wickens (2011, 2012).

Quarterly average of monthly standard devia-

tion of the daily returns of each country's stock

This index draws on the frequency of news-

paper references to policy uncertainty; it was built for Germany, France, Italy, Spain and Source

Datastream

www.policyuncertainty.com

EMU by Baker et al. (2013).

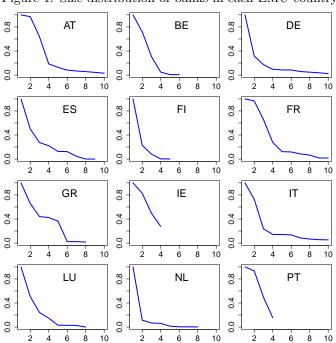

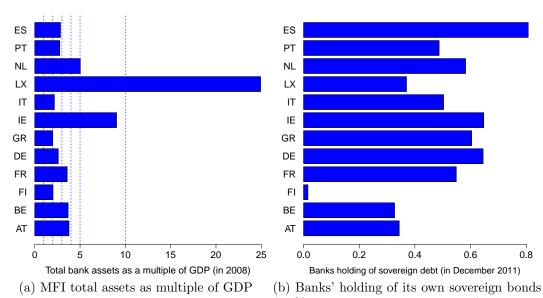

Figure 1: Size distribution of banks in each EMU country

AT: Austria, BE: Belgium, ES: Spain, DE: Germany, FI: Finland, FR: France, GR: Greece, IE: Ireland, IT: Italy, NL: The Netherlands, PT: Portugal, EMU: European Economic and Monetary Union. We show the relative size of banking firms (by total assets in 2010) for each EMU country under study, being the total asset of the biggest bank in a particular country normalized to one. Source: Bankscope.

(as % of total notional outstanding)
MFI: Monetary Financial Institution as classified by Organization for International Co-operation and
Development (OECD). Datasource: OECD, National Central Banks, European Bank Authority stress

test 2011 and Eurostat.

The lines represent different values of DtD for varying combinations of leverage and equity volatility.

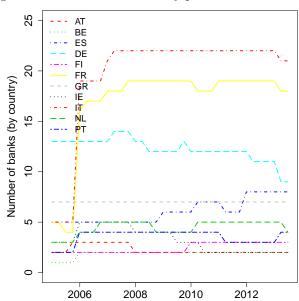

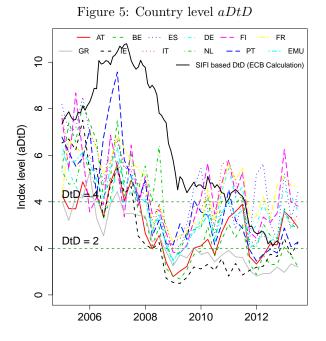

Figure 4: No of banks used every period for each country

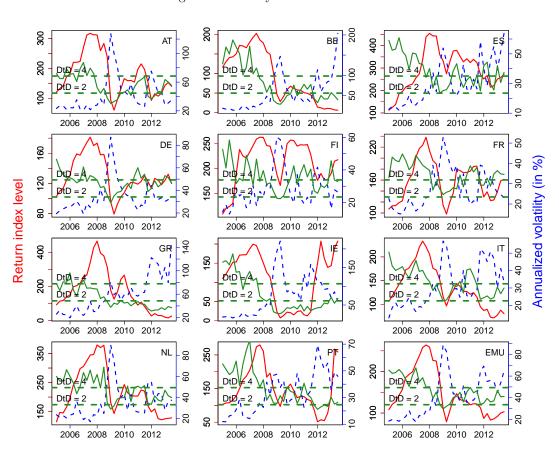

Figure 6: Country-wise indices

The blue, green and red line represent volatility, aDtD and equity index level respectively.

Figure 7: Equity index and aDtD during the crisis

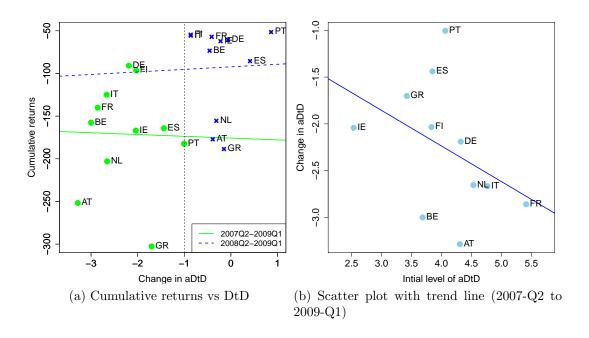

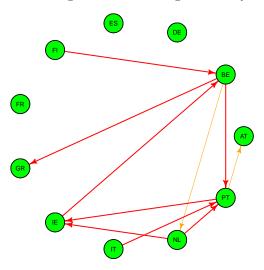

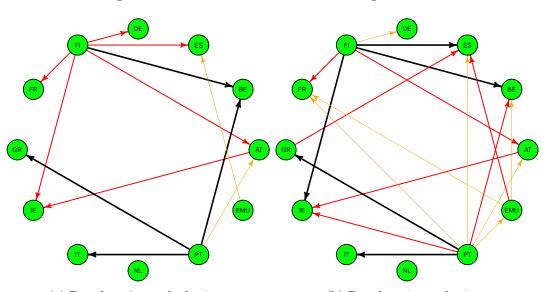

Figure 8: Linkages based on Granger causality tests

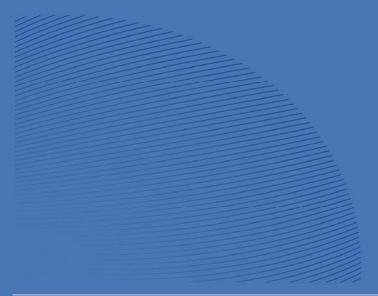

We show the most important directional causalities among the pairs of 12 countries' a DtDs. Red and orange lines represent significance at 10% and 5% level respectively.

Figure 9: Net directional connectedness among aDtDs

(a) Based on 6 months horizon (b) Based on 1 year horizon
We show the most important directional connections among the pairs of 12 countries' aDtDs. Black, red and orange lines represent the first, second and third deciles based on net pairwise directional connectedness derived from Tables 9 and 10.
