“Tracking economic growth by evolving expectations via genetic programming: A two-step approach”

Oscar Claveria, Enric Monte and Salvador Torra
The Research Institute of Applied Economics (IREA) in Barcelona was founded in 2005, as a research institute in applied economics. Three consolidated research groups make up the institute: AQR, RISK and GiM, and a large number of members are involved in the Institute. IREA focuses on four priority lines of investigation: (i) the quantitative study of regional and urban economic activity and analysis of regional and local economic policies, (ii) study of public economic activity in markets, particularly in the fields of empirical evaluation of privatization, the regulation and competition in the markets of public services using state of industrial economy, (iii) risk analysis in finance and insurance, and (iv) the development of micro and macro econometrics applied for the analysis of economic activity, particularly for quantitative evaluation of public policies.

IREA Working Papers often represent preliminary work and are circulated to encourage discussion. Citation of such a paper should account for its provisional character. For that reason, IREA Working Papers may not be reproduced or distributed without the written consent of the author. A revised version may be available directly from the author.

Any opinions expressed here are those of the author(s) and not those of IREA. Research published in this series may include views on policy, but the institute itself takes no institutional policy positions.
Abstract

The main objective of this study is to present a two-step approach to generate estimates of economic growth based on agents’ expectations from tendency surveys. First, we design a genetic programming experiment to derive mathematical functional forms that approximate the target variable by combining survey data on expectations about different economic variables. We use evolutionary algorithms to estimate a symbolic regression that links survey-based expectations to a quantitative variable used as a yardstick (economic growth). In a second step, this set of empirically-generated proxies of economic growth are linearly combined to track the evolution of GDP. To evaluate the forecasting performance of the generated estimates of GDP, we use them to assess the impact of the 2008 financial crisis on the accuracy of agents’ expectations about the evolution of the economic activity in 28 countries of the OECD. While in most economies we find an improvement in the capacity of agents’ to anticipate the evolution of GDP after the crisis, predictive accuracy worsens in relation to the period prior to the crisis. The most accurate GDP forecasts are obtained for Sweden, Austria and Finland.

We would like to thank Johanna Garnitz at the Ifo Institut für Wirtschaftsforschung München for providing us the data used in the study. This research was supported by the projects ECO2016-75805-R and TEC2015-69266-P from the Spanish Ministry of Economy and Competitiveness.
1. Introduction

Evolutionary computation can be regarded as a subfield of artificial intelligence and soft computing centred around a family of algorithms for global optimization inspired by biological evolution, as they adopt principles of the theory of natural selection to problem solving (Fogel, 2006). These algorithms are known as evolutionary algorithms (EAs). Evolutionary computation is increasingly used in economic research (Acosta-González and Fernández-Rodríguez, 2014; Claveria et al. 2018a,b; Ramos-Herrera and Acosta-González, 2017).

There are different types of EAs. The most commonly used EA in optimization problems is the genetic algorithm (GA) developed by Holland (1975). A generalization of GAs that expresses the solution in the form of computer programs was proposed by Cramer (1985) and is known as genetic programming (GP). This more general representation scheme allows the model structure to vary during the evolution. Whereas GAs code potential solutions by means of fixed length binary string representations, GP uses tree-structured, variable length representations suitable for non-linear empirical modelling.

Empirical modelling is based on the development of mathematical models from experimental data, which implies finding both the structure and the parameters of the model simultaneously. Koza (1992) proposed a novel approach to empirical modelling based on symbolic regression (SR) via GP. This modelling technique is based on the specification of any regression model (linear regression, radial basis functions, support vector machines, kriging, etc.) and then searching the space of mathematical expressions that best fit a given dataset. This search process is usually characterised by a trade-off between accuracy and simplicity. Koza (1992) proposed using GP to find the best single computer program that solves a given SR problem. This approach is especially useful to find patterns in large data sets, where little or no information is known about the system.

In this study we implement a SR via GP approach to find the relationship between a wide range of expectational variables and economic growth. We follow a two-step methodology proposed by Claveria et al. (2016b, 2017a) to derive mathematical functional forms that optimally combine survey variables to best fit the actual evolution of the economic activity in 28 countries of the OECD. We make use of survey expectations from the World Economic Survey (WES) carried out by the CESIfo Institute for Economic Research.
Expectations about the state of the economy are a key factor in economic modelling. Agents’ expectations are collected through tendency surveys. Business and consumer tendency surveys ask respondents whether they expect a variable to rise, to remain constant, or to fall. The relationship between quantitative data and agents’ expectations was first formalised by Anderson (1952) and Theil (1952), who regressed the actual average percentage change of an aggregate variable on the percentage of respondents expecting a variable to rise and to fall. The theoretical framework designed for the quantification of these percentages was initially based on the existence of an interval around zero within which respondents perceive there are no significant changes in the variable. Thus, they answer that they expect a certain variable to go up (or down) to the extent that the mean of their subjective probability distribution lies beyond a threshold level, known as the limit of the indifference interval. Carlson and Parkin (1975) developed this approach by using a normal distribution, and by assuming unbiasedness over the sample period to estimate the difference limen. This approach was latter extended by Pesaran (1984, 1985), who allowed the model for an asymmetrical relationship between the actual average percentage change and the agents’ changes in periods of growth.

By matching individual responses with realisations, several authors have further explored this relationship at the micro level (Białowolski, 2016; Lui et al., 2011a, 2011b; Mitchell et al., 2002, 2005a, 2005b; Mokinski et al., 2015). Müller (2010) proposed a variant of the Carlson-Parkin method with asymmetric and time invariant thresholds. Breitung and Schmeling (2013) found that the introduction of asymmetric and time-varying thresholds was key in order to improve the forecast accuracy of quantified survey expectations, while the individual heterogeneity across forecasters played a minor role. Using household-level data from the University of Michigan, Lahiri and Zhao (2015) found strong evidence against the threshold constancy, symmetry, homogeneity, and overall unbiasedness assumptions of the Carlos-Parkin method.

Experimental expectations generated by Monte Carlo simulations have also been used to delve into the relationship between individual expectations and their quantitative equivalent. Common (1985) generated simulated expectations to test the rational expectations hypothesis. Simulation experiments have also been used to assess the forecasting performance of different quantification methods of survey expectations. By means of individual computer-generated expectations, Claveria (2010) compared the forecasting performance of the main quantification methods, while Löffler (1999) and Terai (2009) estimated the measurement error introduced by the Carlson-Parkin method.
The link between survey expectations and quantitative data at the aggregate level has been widely investigated (Abberger, 2007; Batchelor and Dua, 1998, 1992; Bergström, 1995; Berk, 1999; Bovi, 2013; Bruestle and Crain, 2015, Bruno, 2014; Claveria et al., 2007; Claveria et al., 2016a, 2017b; Dees and Brinca, 2013; Driver and Urga, 2004; Graff, 2010; Hansson et al., 2005; Jean-Baptiste, 2012; Kauppi et al., 1996; Leduc and Sill, 2013; Lee, 1994; Lehmann and Wohlrabe, 2017; Mittnik and Zadrozny, 2005; Nardo, 2003; Nolte and Pohlmeier, 2007; Pesaran and Weale, 2006; Qiao et al., 2009, Rahiala and Teräsvirta, 1993; Robinsonov et al., 2012; Smith and McAleer, 1995; Sorić et al., 2013; Vermeulen, 2014; Wilms et al., 2016). Since survey data are approximations of unobservable expectations, they inevitably entail a measurement error. As a result, in spite of the great body of research in this field, there is no consensus in the literature about the usefulness of the information content of survey expectations.

On the one hand, Klein and Özmucur (2010) analysed the role of survey expectations in 26 European countries, and found that they improved the forecasting performance of autoregressive time series models. In a similar sense, Schmeling and Schrimpf (2011) found that survey-based measures of expected inflation were significant predictors of future aggregate stock returns in France, Germany, Italy, the UK, the US and Japan, both in-sample and out-of-sample. Making use of survey expectations of 12 European countries, Ghonghadze and Lux (2012) obtained a superior out-of-sample forecasting performance with a canonical opinion dynamics model than with univariate time series models. Jonsson and Österholm (2012) analysed the inflation expectations formation process in Sweden using survey expectations, obtaining a poor forecasting performance that could be partly attributable to a mismeasurement of expectations. However, Österholm (2014) found that survey-based expectations improved the out-of-sample forecasting performance of GDP growth predictions in Sweden.

Martinsen et al. (2014) constructed factor models based on disaggregate survey data to forecast inflation, unemployment and GDP in Norway. The authors obtained the most accurate results for GDP growth. Girardi (2014) found that survey expectations contained relevant information about business cycle developments in the Euro Area (EA), especially around periods of extreme cyclical swings. Guizzardi and Stacchini (2015) showed that the inclusion of business survey indicators in time series models increased the forecasting accuracy of the baseline models. In a recent study, Altug and Çakmakli (2016) generated inflation forecasts by combining data on survey expectations with the inflation target set by central banks, finding the former to increase the predictive power of the models.
Although these studies use a wide range of econometric techniques, none of them assesses the relationship between both official quantitative data and qualitative survey expectations by means of evolutionary methods. In this research we design a SR experiment and use evolutionary computation to find the optimal combinations of survey expectations that best fit the actual evolution of year-on-year growth rates of GDP. In a recent study, Lahiri and Zhao (2015) found a significant improvement in agents’ expectations accuracy during periods of uncertainty. This finding has also led us to assess the impact of the 2008 financial crisis on agents’ ability to forecast the evolution of economic activity. Hence, we use the estimates of GDP in 28 OECD economies and compare them to a baseline model by means of the mean absolute scaled error (MASE) proposed by Hyndman and Koehler (2006).

The rest of the paper is organized as follows. The next section reviews the existing literature and describes the methodological approach and the experimental set up. In Section 3 we describe the data and present the empirical results. Finally, Section 4 provides some concluding remarks.

2. Methodology

GP is a soft computing search technique for problem-solving. GP’s tree-structured programs are evolved by means of genetic operators for model approximation. In this study we design a SR experiment in order to derive a set of functional forms that link survey expectations to economic growth. This data-driven regression approach assumes no a priori model. Using EAs that apply Darwinian principles that imitate aspects of biological evolution, such as the principle of survival and reproduction of the fittest, an initial population of computer programs are bred through generations to find a set of analytical functions that best fit the data.

Koza (1992) proposed using GP for implementing SR. In his seminal paper, Koza (1995) applied GP to assess the non-linear “exchange equation”, finding the empirical relationships between the price level, and gross national product, money supply, and the velocity of money. The versatility of this empirical modelling approach has attracted researchers from different areas (Álvarez-Díaz et al., 2009; Bampalexis et al., 2011; Cai et al., 2006; Can and Heavey, 2011; Ceperic et al., 2014; Sarradj and Geyer, 2014; Wu et al., 2008; Yao and Lin, 2009).
Most of the applications of evolutionary computing to economics have been in finance (Goldberg, 1989). For a review of the applications of GAs for financial forecasting see Drake and Marks (2002). Acosta-González et al. (2012) used a GA to select the best econometric model for explaining the 2008 financial crisis, and found that the main determinant was the percentage of bank claims on private sector over deposits in the year 2006. By means of a computational search methodology based on GAs, Acosta-González and Fernández-Rodríguez (2014) selected the optimal financial ratios employed in a logit model to forecast bankruptcy in the Spanish building industry using annual public accounting information. Álvarez-Díaz and Álvarez (2005) used GP to forecast exchange rates of the yen and the pound to the US dollar. Based upon its performance in eight stock markets and eight foreign exchange markets during three consecutive test periods, Chen et al. (2008) thoroughly analysed the application of GP to financial trading, shedding some light on how GP performance could be connected to the trending and cyclical properties of financial data. Huang et al. (2015) presented a novel methodology for pairs trading using GAs.

Larkin and Ryan (2008) applied GP to nowcast stock prices using ordinal news sentiment data generated in real time by classifying financial news into positive, negative and neutral. The authors found that GP effectively predicted large intraday price jumps on the Standard & Poor 500 return index (S&P 500) up to an hour before they occurred without using current market prices information. Sheta et al. (2015) modelled the S&P 500 using multi-gene SR. Multi-gene SR is a special variation of the classic GP algorithms where each symbolic model is represented by a number of GP trees weighted by a linear combination. The method was used to evolve linear combinations of non-linear functions of 27 input variables, obtaining robust results when tracking the S&P 500 index in a weekly basis. Ramos-Herrera and Acosta-González (2017) evaluated the factors explaining exchange rate stability in 17 economies of the European Union (EU) making use of GAs. Among the higher impact factors, the authors found that variables measuring competitiveness, including agents’ expectations, clearly stood out due to their repeated presence in the different models. Vasilakis et al. (2013) presented a GP-based technique to predict returns in the trading of the euro/dollar exchange rate based on historical data and assessed its forecasting performance relative to four different approaches, obtaining the highest trading performance with the proposed method. Wilson and Banzhaf (2009) compared a developmental co-evolutionary GP approach to standard linear GP for interday stock prices prediction.
Applications of evolutionary computation in economics are more recent and scarce. See Chen and Kuo (2002) for a classification of the literature on the application of evolutionary computation to economics and finance. By means of GAs, Acosta-González et al. (2014) selected the best econometric model for explaining the determinants of the size of the shadow economy using data from 38 economies. The authors found that the main determinants of the shadow economy were: taxes on capital gains of individuals, corporate taxes on income, profits and capital gains, domestic credit, bank secrecy, ethnic fractionalization, urban population, globalization, corruption and the socialist legal origin of country. Chen et al. (2010) introduced GP in a vector error correction model for macroeconomic forecasting. By means of SR via Pareto GP, Kotanchek et al. (2010) provided some insight into GDP forecasting. Duda and Szydlo (2011) applied an improved version of GP known as gene expression programming (GEP) (Ferreria, 2011) to develop a set of economic forecasting models.

Kapetanios et al. (2016) assessed the forecasting performance of GAs and two other heuristic optimisation algorithms to forecast quarterly GDP growth and monthly inflation in the EA based on a large set of 195 monthly indicators. The authors found that variable selection based on heuristic optimisation outperformed variable reduction methods (principal components, partial least squares, and Bayesian shrinkage regression). See Milutinović et al. (2017) and Petković (2015) for alternative heuristic optimisation strategies. Klůčik (2012) used SR via GP in the estimation of total exports and imports to Slovakia. Krömer et al. (2013) presented an application of GP to the evolution of fuzzy rules based on the concept of extended Boolean queries. In their approach, fuzzy rules are used as symbolic classifiers learned from data and used to label data records and to predict the value of an output variable. The authors used GP to find fuzzy rules labelling faulty products in a steel processing plant. Kronberger et al. (2011) made use of SR to identify variable interactions between 33 economic indicators in order to estimate the evolution of prices in the US. In a recent study, Marković et al. (2017) assessed the role of ten science and technology factors as inputs for GDP growth prediction in 28 EU countries. The authors compared the predictive accuracy of GP and other soft computing methods to that of extreme learning machines (ELMs) (Huang et al., 2006), and obtained the highest accuracy with ELMs were initially proposed as learning algorithms for single-hidden layer feedforward neural networks characterised by fast training time. Yang et al. (2015) applied a data-driven approach based on SR to predict oil production in the US, using data from the 48 lower states since 1859.
Among recent developments in evolutionary computation, Zelinka (2005) introduced analytical programming, and showed its ability to synthesize suitable solutions (programs) in SR. Maschek (2010) developed a two-level learning (or self-adaptation) mechanism and evaluated how it affected an economic application of GAs. Vladislavleva et al. (2010) evaluated different ways of improving SR by incorporating weights into the fitness function. Waltman et al. (2011) examined to what extent the use of binary encoding strategies influence the results produced by GAs. Peng et al. (2014) proposed an improved GEP algorithm especially suitable for dealing with SR problems. Gandomi and Roke (2015) compared the forecasting performance of ANN models to that of GEP techniques. See Dabhi and Chaudhary (2015) and Poli et al. (2010) for a review of the main issues related to GP.

GP allows to find patterns in large data sets. This feature is particularly indicated when little or no information is known about the system. While in evolutionary programming (Fogel, 1966) the structure of the program to be evolved remains fixed, GP simultaneously evolves the structure and the parameters of the models. In this study we use GP to formalise the interactions between a set of indicators of survey expectations that best fit the evolution of economic activity. As there is an arbitrary functional relationship between this set of survey variables (Table 1), we link all of them to the actual percentage growth rate of GDP by means of a SR model:

\[ y_{it} = f(x_{12i}, x_{11i}, x_{10i}, x_{9i}, x_{8i}, x_{7i}, x_{6i}, x_{5i}, x_{4i}, x_{3i}, x_{2i}, x_{1i}) \]  

where \( x_{1i}, K, x_{12i} \) are the different survey variables, and \( y_{it} \) is a scalar referring to the year-on-year growth rate of quarterly GDP for country \( i \) at time \( t \). We divide the set of survey variables into three types: judgements about the present economic situation \( (x_{1i}, x_{2i}, x_{3i}) \), perceptions about the present economic situation compared to last year \( (x_{4i}, x_{5i}, x_{6i}) \), and expectations for the next six months about the economic situation \( (x_{7i}, x_{8i}, x_{9i}) \) and the foreign trade volume \( (x_{10i}, x_{11i}, x_{12i}) \). See Table 1.
By means of GP we evolve the resulting symbolic mathematical expressions until a stopping criterion is reached, be it a predetermined value of the fitness function or a given number of generations. We want to note that there is a trade-off between fitness and complexity. To deal with the growth in the complexity of the SR function we introduce a term that penalizes the functions that exceed a given number of terms. In this study we have chosen a maximum number of 150 generations as a stopping criterion. In Table 2 we summarize the steps for implementing GP.

</tr>
</tbody>
</table>

1. Creation of an initial population of programs – First, in order to start the process we create an initial population of 1,000 programs.

2. Evaluation of fitness for each program – An error metric is calculated for each member of the population. We use the Root Mean Square Error (RMSE) as a fitness function.

3. Selection of a reproduction strategy – From the existing strategies for the selection of parents for replacement, which are the programs used to create offspring programs, we
use the tournament method so as to guarantee diversity in the population. This method
is based on the selection of the fittest individual in each tournament among a group of
individuals chosen at random from the population. One of the main advantages over other
alternative methods is that the selection pressure can be easily adjusted and it is code-
efficient.

(4) Application of genetic operators – Genetic operators (crossover and mutation) are
applied to the parents selected on the basis of the fitness function. Crossover consists on
the recombination of randomly chosen parts of parents, while mutation on randomly
altering a part of a parent.

(5) Determination of constants – We include the automatic generation of constants
provided by the GA. This set of constants is optimised after a number of generations to
avoid the search path to deviate from the optimum.

(6) Creation of a new population – Generation after generation, the fitness of the
population increases, as steps three and four are repeated until the creation of a new
population when a required minimal fitness is achieved. In this experiment we have
chosen a maximum number of 150 generations as a stopping criterion.

The output of this process is a set with the best individual functions from all
generations. In this study we have used the open source Distributed Evolutionary
Algorithms Package (DEAP) framework implemented in Python (Fortin et al. 2012; Gong
et al. 2015).

3. Results

In this section we present the results of the experiment. The SR has been estimated using
survey data from the CESifo WES for 28 countries of the OECD, and GDP data retrieved
from the OECD web (https://data.oecd.org/gdp/quarterly-gdp.htm#indicator-chart). The
sample period goes from the second quarter of 2000 to the first quarter of 2014. The WES
is carried out by the CESifo Institute for Economic Research. The questionnaire asks
respondents whether they expect their country’s general economic situation to get better,
worse, or to remain unchanged.

Qualitative responses are transformed by means of a grading procedure consisting in
giving a rank of 9 to positive replies, of 5 to indifferent replies, and of 1 to negative replies
(CESifo World Economic Survey, 2011). Survey results are published as aggregated data
by country, weighting the results according to the country’s share of trade worldwide. See Henzel and Wollmershäuser (2005), Stangl (2007, 2008), and Hutson et al. (2014) for a detailed analysis of WES data. The Ifo makes use of these data to construct the Economic Climate Index (ECI). The ECI is an aggregate indicator obtained as the arithmetic mean of assessments of the general economic situation and the expectations for the economic situation in the next six months. The trend in the ECI tends to correlate closely with the actual business-cycle trend measured in annual growth rates of real GDP (Garnitz et al., 2015). In Table 3 we present a descriptive analysis of the ECI for the 28 economies analysed in this study.

The GP-generated functions in Table 4 can be regarded as building blocks, which are then introduced as regressors of GDP growth so as to obtain the coefficients used to generate the optimal linear combination to estimate the evolution of economic growth. In order to assess the accuracy of the forecasts of GDP, we first compare the evolution of the obtained estimations of economic growth to that of the ECI. Fig. 1 compares the evolution of the GR-based estimates to that of the year-on-year growth rates of GDP and the ECI. We can observe that the estimates seem to correlate closely with the actual oscillations of GDP. In most economies agents’ expectations seem to advance turning points, especially regarding the 2008 financial crisis. The severity of the crisis varies across countries, being Estonia, Latvia, and Lithuania the economies showing the highest percentages of decrease in the activity. At the opposite end, Norway and Poland show the lowest decline in terms of GDP growth, being the countries in which the GR-generated forecasts from agents’ expectations more clearly overestimate the extent of the crisis.
Fig. 1a. Evolution of year-on-year GDP growth rates vs. survey-based economic indicators (2000:Q2-2014:Q1)

1. Note: The black dotted line represents the year-on-year growth rate of GDP in each country. The grey line represents the evolution of the scaled ECI (secondary axis). The black line represents the evolution of the proposed indicator.

After the graphical analysis, we evaluate the in-sample forecasting performance of the quantified expectations by comparing them to a benchmark model in order to compute the MASE. This measure of forecast accuracy was developed by Hyndman and Koehler (2006), who proposed scaling the forecast errors by the in-sample mean absolute error (MAE) obtained with a random walk. As official data are published with a delay of more
than a quarter with respect to survey data, we use two-step ahead naïve forecasts as a baseline. The MASE statistic presents several advantages over other forecast accuracy measures. First, it is independent of the scale of the data. Second, it does not suffer from some of the problems presented by other relative measures of forecast accuracy such as the relative MAE. Finally, it is easy to interpret: values larger than one are indicative that the GP-based forecasts are worse than the average prediction computed in-sample with the baseline model.

If we denote the forecast error obtained by means of GP as $e_t = y_t - \hat{y}_t$, the scale error is defined as:

$$q_t = \frac{e_t}{\frac{n}{n-1} \sum_{i=3}^{n} |y_i - y_{t-2}|}$$

Hence, the MASE is obtained as the mean of $q_t$, $MASE = \text{mean}(q_t)$.

With the aim of assessing the potential influence of the 2008 financial crisis on the forecasting accuracy of GP-generated estimates of GDP, we re-compute the MASE differentiating between the pre-crisis sub-period (2000-2007), the crisis (2007-2010), and the post-crisis sub-period (Table 5).

The results in Table 5 show that the most remarkable improvement of the survey-based estimates relative to the benchmark model are obtained in Sweden, Austria, and Finland, as opposed to Croatia and Lithuania. When splitting the results in sub-periods, we find that the accuracy of the estimates of GDP significantly worsens during the crisis in most countries, with the exception of Austria, Czechia, France, Ireland, Portugal, the UK and the US. When comparing the accuracy of agents’ expectations between the post-crisis and the pre-crisis years, we obtain mixed results. This mixed evidence is in line with previous research. While Lahiri and Zhao (2015) found a significant improvement in agents’ expectations accuracy during periods of uncertainty and Łyziak and Mackiewicz-Łyziak (2014) showed that the 2008 financial crisis period led to a decrease in expectational errors in transition economies, Erjavec et al. (2015) found that consumers’ expectational bias regarding inflation in Croatia diminished in times of lower price volatility.

Notes: * MASE stands for the Mean Absolute Scaled Error. In this study we propose scaling the errors by the in-sample MAE obtained with the Naïve method for two-step ahead forecasts (as official data are published with a delay of more than a quarter with respect to survey data). Values larger than one (in bold) indicate worse predictions than the average forecast computed in-sample with the Naïve method.
4. Concluding remarks and future work

Evolutionary computation is increasingly being used for economic applications. In this study we implement GP to find the most fitted mathematical functional forms linking survey expectations to economic growth. By linearly combining the output of this GP-generated set of models, we estimate the evolution of GDP in 28 OECD economies. The proposed approach demonstrates the potential of survey expectations for economic forecasting and circumvents the issue of quantifying qualitative expectations on the direction of change. Thus, this data-driven method for modelling survey-based agents’ expectations avoids making assumptions about the subjective probability distribution of respondents.

SR via GP allows selecting the fittest models of interaction between agents' expectations and the official quantitative series they refer to. As a result, the evolution of the GP-generated forecasts correlates closely with the actual oscillations of the economic activity and with other official economic indicators such as the ECI. This result suggests that this empirical approach to model survey expectations on the direction of change may provide gains in forecast accuracy.

We have also analysed the impact of the 2008 financial crisis on the accuracy of agents’ expectations by assessing the capacity of GP-generated estimates of GDP to anticipate future economic growth. We have found that the crisis period has led to a deterioration in the forecasting performance of agents’ expectations in most economies.

Despite the versatility of the proposed GP approach for modelling survey-based expectations to estimate economic growth, some aspects have been left for further research. We have not evaluated to what extent the forecasting performance of GP predictions could have been improved by increasing the maximum number of generations. There is also the question of whether the implementation of improved adaptive algorithms, such as Ferreira’s gene expression programming or Zelinka’s analytical programming, may improve the forecasting performance of computationally generated economic forecasts. Finally, another issue left for future research is the use of GP-based expectations to assess empirically observed economic relationships such as the Phillips curve, or to test the rational expectations hypothesis.
